Applying linear response and the magnetic force theorem in correlated density functional theory, the intersublattice exchange constants of antiferromagnetic Eu are calculated and found to vanish near the pressure of $P_c = 82$ GPa, just where magnetic order is observed experimentally to be lost. The Eu $4f^7$ moment remains unchanged at high pressure, again in agreement with spectroscopic measurements, leaving the picture of perfect frustration of interatomic Ruderman-Kittel-Kasuya-Yoshida couplings in a broad metallic background, leaving a state of electrons strongly exchange coupled to arbitrarily oriented, possibly quasistatic local moments. This strongly frustrated state gives way to superconductivity at $T_c = 1.7$ K, observed experimentally. These phenomena, and free energy considerations related to correlations, suggest an unusual phase of matter that is discussed within the scenarios of the Doniach Kondo lattice phase diagram, the metallic spin glass class, and itinerant spin liquid or spin gas systems.

DOI: 10.1103/PhysRevLett.122.057201

The behavior of local moments and their ordering as some external parameter (volume, electron density, magnetic field) varies lies at the root of several paradigmatic phenomena, viz. the Kondo effect, heavy fermion superconductivity, spin liquid, and spin glass phases. The $4f$ shell in lanthanides (Ln) has provided a unique platform for the study of several of these issues. Ce and Yb compounds, with their $4f$ level near the Fermi energy, show $4f$-conduction electron coupling that can be tuned across the Doniach critical point from antiferromagnet (AFM) to conduction electron coupling that can be tuned across a linear decrease in the magnetic ordering temperature $T_m$. This first order disappearance of order represents an avoidance of the antiferromagnetic (AFM) quantum critical point that is actively studied in weak AFMs [12]. This paramagnetic (PM) phase, with its SC ground state in the midst of disordered spin, may provide a platform for learning more about Ln magnetic interactions, and perhaps more general issues about neighboring phases near a QCP, possibly including a spin liquid or spin gas phase coexisting with SC.

This behavior can be compared with that of Yb. Under pressure, Yb undergoes a valence transition [13–16] from divalent $f^{14}$ to somewhere near trivalent $f^{13}$ through a continuous evolution through intermediate valence and emergence of a local moment, a crossover that has been simulated successfully by dynamical mean field calculations [16] up to 40 GPa. Recently Song and Schilling have reported [17] that Yb, notwithstanding its $f^{13}$ local moments, becomes superconducting in the 1.4–4.5 K range at 80 GPa and above. This behavior has parallels with, but distinctions to, that of Eu, to which we return to in the discussion.

The PM phase above $P_c$ is unusual in having large spins on a dense periodic lattice interacting via RKKY Heisenberg exchange (the spins are isotropic) yet they do not order, a signature of a type of frustration that is not apparent. Following the classification of Sachdev and Read [18], we refer to this as the metallic quantum paramagnet (MQPM) phase. Beyond the question of (dis)ordering, there is the perplexing issue of superconductivity in a metal with disordered strong local moments. A simple scenario would be that Eu would be driven through a valence transition to the nonmagnetic $f^6 J = 0$ configuration, in which case there is no magnetic impediment to superconducting pairing, viz. the isovalent rare earth metal Y becomes an impressive superconductor under pressure, with $T_c$ up to 17 K [19]. We find that Eu, unlike Yb, is not near a change in valence up to 100 GPa or more.

While early studies suggested a valence transition below 80 GPa [20], more recent x-ray absorption confirm that Eu retains its $f^7$ moment even in the SC phase above 82 GPa.

line{7} lattice constant (a) bcc, (b) hcp, and (c) $Pnma$. The lattice
line{7} structures were obtained from experiments. Red dashed lines
line{7} indicate the $V/V_0$ ratio of pressures where the structures are
line{7} confirmed stable in experiments, as given by Bi et al. [5].

[17,21] in agreement with our calculations. The SC phase is
line{7} then of an exotic type in which pairing occurs within a dense
line{7} lattice of large but disordered and uncompensated moments. These
line{7} questions have led us to perform systematic calculations of the electronic structure and magnetic coupling of Eu at pressures up to the 100 GPa range.

Like all Ln metals, Eu displays structural transformations with increasing pressure. Structural information is provided in the Supplemental Material (SM [22]). The volume decrease $V/V_0$ ratio ($V_0$ is the ambient volume) and the regions of stability of the three phases [5] are shown with the magnetic structures in Fig. 1. The evidence is that Eu displays AFM order from ambient to $P_c$ = 82 GPa. At $P_c$, magnetic order vanishes and superconductivity emerges with critical temperature $T_c = 1.7$ K, increasing with pressure up to 2.8 K at 142 GPa [7]. As recently reported [6] and as we confirm from our calculations, the large moment on Eu persists (the $f^7$ moment in Gd is calculated [23] to persist to 500 GPa), making the interplay between large but disordered moments and SC, and its dependence on pressure, unresolved issues.

Our density functional theory (DFT) calculations employ the full potential linearized-muffin-tin-orbital method (LMTO) [24]. The local spin density approximation (LSDA) with Hubbard U correction (LSDA + U) is applied to the localized 4f shell orbitals of Eu, using the localized limit functional implemented in the LMTO package in rotationally invariant fashion [25,26]. A reasonable value is $U = 6$–7 eV at ambient pressure [27]; we have used $U = 7$ eV and $J = 1$ eV at zero pressure, and at high pressure we investigate smaller values of $U$. We use LSDA + U rather than LDA + U because the spin-density mediated intraatomic $f - d$ Hund’s coupling that polarizes the conduction electrons is important to include and assess. See Supplemental Material SM [22] for additional information.

Interatomic RKKY exchange constants are known to extend out to dozens of neighboring shells in Eu [27,28]. Instead we focus on the AFM sublattice exchange constants, which are linear combinations of interatomic exchange constants out to arbitrary distance. An effective and efficient method is to use linear response theory and the magnetic force theorem [29]. Consider the electronic Kohn-Sham Hamiltonian $H_{KS} = T + V_0 + V_{sp}$, where $T$ is kinetic energy, $V_0$ is the spin-independent potential, and $V_{sp}$ is the spin-dependent potential including the contribution from $U$. We write $V_{sp} = \hat{\sigma} \cdot \mathbf{B}$, $\mathbf{B} = [v_{xc,j}^{\uparrow}(r) - v_{xc,j}^{\downarrow}(r)]\hat{B}$, where $\hat{\sigma}$ is the electron spin vector of Pauli matrices. $\mathbf{B}$ appears as an effective Zeeman field arising from the spin-dependent exchange-correlation potential $v_{xc}$. If one rotates the moment on AFM sublattices $\tau, \tau'$ in unit cells $\mathbf{R}, \mathbf{R'}$ by infinitesimal angles $\delta \theta R, \delta \theta \tau^{\prime}$, respectively, the second order energy difference is related to the exchange constants by

$$J_{\tau \tau'}^{\alpha \beta} = \frac{\delta^2 E}{\partial \theta_R \partial \theta_{\tau'}^{\beta}} = \sum_q J_{\tau \tau'}^{\alpha \beta}(q) \tilde{e}^{q(R-R')},$$

$$J_{\tau \tau'}^{\alpha \beta}(q) = \sum_{kff} B_{kj,k+q,q}^{\alpha \beta} B_{kj,k+q,q}^{\beta \alpha} f_{k-j} - f_{k+q+j},$$

$$B_{kj,k+q,q}^{\alpha \beta} = \langle k | [\sigma \times \mathbf{B}_{\tau \tau'}]| k + q+j \rangle.$$
significant van Hove singularities in the density of states nor to identifiable structure in $J_{ij}$ versus pressure. While spiral magnetic order is commonly identified with nesting of sheets of Fermi surface, a stable AFM order while the Fermi surface evolves argues against any nesting origin of ordering.

Equations (2)–(4) were used to calculate the sublattice exchange constants $J_{\tau\tau}$ based on the AFM ordered state. With two up and two down spins, symmetry reduces the number of constants to three, viz. up1-up1, up1-down1, up1-down2, denoted below by $J_{12}$, $J_{13}$, $J_{14}$, respectively. The RKKY expression includes momentum-conserving virtual excitations, with those near the Fermi level having larger weight. In the $q \to 0$ limit, inter-sub-lattice exchange constants contain distinct intraband and interband terms (for general $q$ there is no distinction). The energy denominator makes exchange coupling somewhat sensitive to Fermi surface nesting, and several examples of incommensurate (often spiral) order in lanthanides have been traced back to Fermi surface calipers. The interband contribution will be continuous and more slowly varying than the intraband contribution. The calculated $J_{\tau\tau}(q=0)$ couplings versus pressure are shown in Fig. 3 for $U = 5, 6, 7$ eV. For bcc and hcp Eu, see Figs. 3(a) and 3(b), respectively, the single sublattice coupling is FM for $J_{12}$ and AFM in sign for the other two, and each increases monotonically in magnitude over the range of interest.

The behavior in the high pressure $Pnma$ structure is different. In Figs. 4(c)–4(f) $J_{12}$, $J_{13}$, and $J_{14}$ at $\vec{q} = 0$ are shown, with increasing pressure and for $U = 4, 5, 6$ eV. $U$ affects primarily the magnitude, and does not change the behavior as volume is reduced. The trend with increasing pressure is for all three sublattice couplings to decrease in magnitude and pass through zero nearly simultaneously, signaling a collapse of the spin-wave spectrum and frustration of sublattice coupling rather than frustration of magnetic order. This trend is nearly independent of the value of $U$; the collapse occurs at somewhat lower pressure as $U$ is decreased. $U$ is expected to decrease under pressure from the $U = 6–7$ eV value that is realistic [27] at ambient pressure. Note that the curves in Figs. 3(c)–3(f) become unphysical beyond $P_c$. It is not unusual in highly frustrated magnets to encounter a range of exchange couplings for which AFM order vanishes. Eu thus provides a contrast to the Fe pnictides where impact of magnetic interactions on the phase diagram has been actively studied. Our methods applied to Fe pnictides led to (1) effective short-range coupling, and (2) AFM order that vanishes due to first neighbor ($J_1$) and second neighbor ($J_2$) coupling as $J_1/2J_2$ approaches unity [30,31]. Such a $J_1 - J_2$ model near frustration, with spins damped by

FIG. 2. The Fermi surfaces of Eu at the relative volumes (with respect to that at 75 GPa) of +6%, 0, −4%, and −10%. At all volumes the surfaces are large and multisheeted, varying through changes in topology with the only effect being the decrease in exchange constants and hence the ordering temperature, which vanishes around 82 GPa.

The behavior in the high pressure $Pnma$ structure is different. In Figs. 4(c)–4(f) $J_{12}$, $J_{13}$, and $J_{14}$ at $\vec{q} = 0$ are shown, with increasing pressure and for $U = 4, 5, 6$ eV. $U$ affects primarily the magnitude, and does not change the behavior as volume is reduced. The trend with increasing pressure is for all three sublattice couplings to decrease in magnitude and pass through zero nearly simultaneously, signaling a collapse of the spin-wave spectrum and frustration of sublattice coupling rather than frustration of magnetic order. This trend is nearly independent of the value of $U$; the collapse occurs at somewhat lower pressure as $U$ is decreased. $U$ is expected to decrease under pressure from the $U = 6–7$ eV value that is realistic [27] at ambient pressure. Note that the curves in Figs. 3(c)–3(f) become unphysical beyond $P_c$. It is not unusual in highly frustrated magnets to encounter a range of exchange couplings for which AFM order vanishes. Eu thus provides a contrast to the Fe pnictides where impact of magnetic interactions on the phase diagram has been actively studied. Our methods applied to Fe pnictides led to (1) effective short-range coupling, and (2) AFM order that vanishes due to first neighbor ($J_1$) and second neighbor ($J_2$) coupling as $J_1/2J_2$ approaches unity [30,31]. Such a $J_1 - J_2$ model near frustration, with spins damped by
conduction electrons, was proposed by Wu et al. [32,33] to account for the quantum critical point versus isoelectronic As → P doping in BaFe$_2$As$_2$. Recently Sapkota et al. [34] reported near-perfect $J_1 - J_2$ frustration in an itinerant metallic system, square lattice CaCo$_{1.86}$As$_2$ tuned (naturally) by Co vacancies. Frustration in Eu is in a stoichiometric lattice with local moments and RKKY interactions, so the mechanism of frustration—volume evolution of many exchange constants—is distinct.

Discussion.—Both experiment and our calculations concur that Eu retains its $f^7$ local moment without valence change [6], and magnetic coupling vanishes at $P_c$. Evidently the evolution of the electronic structure plays a critical role by inducing a AFM-MQPM transition. That the three independent couplings vanish together at $P \approx P_c = 82$ GPa suggests that the Kondo coupling between spin and conduction electrons dominates RKKY coupling [35] and has decreased dramatically with pressure. We have calculated the hybridization function [36] and determined that this is not the case.

A schematic phase diagram based on experimental data is presented in Fig. 4. Magnetic order decreasing to 11 K vanishes at $P_c$, and superconducting electronic order emerges as the ground state of this MQPM. This ground state presents a potentially new phase: a superconducting condensate in the midst of large disordered moments (not compensated by Kondo coupling) below $T_c = 1.7$ K. The character of the transition from AFM order to an MQPM phase at $P_c$ seems intimately related to the question of magnetic correlations in the MQPM phase. In the free energy $F(P,T) = E_{\text{DFT}}[V(P)] + PV_{\text{DFT}}(P) + E_m(P,T) - TS_m(P,T)$ the first two quantities are available from DFT calculations and are linear in $P$ and $T$ independent at low $T$ since (1) no structural change occurs [5], and (2) the magnetic moments remain, only the magnetic order vanishes [6]. The electronic entropy $(\pi^2/3)k_B T N(E_F) \sim (\pi^2/3)k_B T/W$, where the bandwidth is $W = \sim 2-4$ eV, is orders of magnitude smaller than the magnetic terms, and has not been displayed.

The magnetic contributions, $E_m$ and $S_m$ from spin waves in the AFM phase, or spin disorder in the PM phase, must account for the small free energy change across the transition. The difference in entropy between ordered and uncorrelated moments at high temperature is $S^\infty = k_B \ln(2S + 1) = 3k_B \ln 2$ for $S = \frac{7}{2}$. A rough (factor of two) estimate of the entropy of the ordered phase can be taken from the linear spin-wave theory expression $S_{\text{AFM}} = \beta(P)T^3$; $\beta$ is $P$ dependent because it depends on the exchange couplings $(J_{ij})$. The entropy just above $T_N$ is roughly $S^\infty/2$, a common value for AFMs. Equating these at $T_N$, one obtains the change across the transition as temperature is lowered for $P < P_c$

$$\Delta(TS_m(P,T)) \approx \frac{1}{2} S^\infty T \left(1 - \frac{T^3}{T_N(P)^3}\right),$$

which is smooth and small across the magnetic transition but becomes sizable at a somewhat lower temperature.

However, supposing uncorrelated moments for $P > P_c$, the change in entropy across $P_c$ has the same form: the increase in entropy contributes to the loss of magnetic order above $P_c$, with a finite jump for $T < T_N(P_c) = 11$ K but vanishing at $(P_c,T_N)$, giving no driving force for a first order transition at this point in the phase diagram.

The magnetic energy $E_m$ of thermally excited spin waves, $E_m(P,T) = \int d\omega D(\omega,P)n(\omega/T)$ in terms of the spin-wave density of states $D$ and the Bose occupation factor $n(\omega/T)$, is replaced above $P_c$ with contributions depending on the degree of magnetic correlation among the disordered spins. Total lack of correlation is unrealistic, in fact, considerable short-range correlation must survive to leave only a small change in the free energy at $P_c$. The result: the necessary small change in free energy across $P_c$ implies spin correlations in the MQPM phase, possible characterizations being a spin liquid [37] or spin glass [38]. YMn$_3$ and CaCo$_{1.86}$As$_2$ both are magnetic metals that have been discussed as spin liquids [34,39], but unlike Eu they are understood in terms of frustrating short-range interactions.

In closing, we comment on the unconventional electronic state in the SC phase. The scenario that has emerged is that of superconducting pairs coexisting with a spin glass or spin liquid magnetic system, presumed classical given the large value of the moments. With negligible quantum fluctuation and the temperature being low compared to other scales, one has pairing in the midst of quasistatic spins. Superconductivity in the context of spin glasses has been discussed, for example by Galitski and Larkin [40], and an example proposed by Davidov et al. [41]; however spin glasses are nearly always treated in the dilute impurity limit where positional disorder is a central issue, whereas
the spins in Eu are dense and periodic. Our calculated exchange splitting of the Eu $d$ bands for ferromagnetic alignment indicates a local on site $f - d$ Hund’s exchange strength near 1 eV, corresponding to a FM Kondo coupling of $K = 1.0/\left(\frac{7}{2} \times \frac{7}{2}\right) \sim 0.5$ eV. This strong coupling suggests comparable spin-disorder broadening of the conduction bands, hence washing out of the Fermi surface. Spin-disorder is normally destructive of pairing, unless the mechanism actually proceeds through, and depends on, the dynamic spin system. Such pairing, if it is responsible, lies in a different regime in Eu than for the cuprates, Fe-based superconductors, and heavy fermions, where magnetic fluctuations of small moments are intimately mixed into the conduction states. Yb at high pressure, as discussed in the introduction, presents a SC phase that may possess similarities to that of Eu.
