(Received 3 October 2012; published 12 March 2013)

The orthorhombic perovskite NaOsO₃ undergoes a continuous metal-insulator transition (MIT), accompanied by antiferromagnetic (AFM) order at $T_\text{c} = 410$ K, suggested to be an example of the rare Slater (itinerant) MIT. We study this system using $ab$ initio and related methods, focusing on the origin and nature of magnetic ordering and the MIT. The rotation and tilting of OsO₆ octahedra in the GdFeO₃ structure result in moderate narrowing of the bandwidth of the $t_{2g}$ manifold but sufficient to induce flattening of bands and AFM order within the local spin density approximation, where it remains metallic but with a deep pseudogap. Including on-site Coulomb repulsion $U$, at $U_r \approx 2$ eV a MIT occurs only in the AFM state. Effects of spin-orbit coupling (SOC) on the band structure seem minor, as expected for a half-filled $t_{2g}$ shell, but SOC doubles the critical value $U_r$ necessary to open a gap and also leads to large magnetocrystalline energy differences in spite of normal orbital moments no greater than 0.1 $\mu_B$. Our results are consistent with a Slater MIT driven by magnetic order, induced by a combination of structurally induced band narrowing and moderate Coulomb repulsion, with SOC necessary for a full picture. Strong $p$-$d$ hybridization reduces the moment, and when bootstrapped by the reduced Hund’s rule coupling (proportional to the moment) gives a calculated moment of $\sim 1 \mu_B$, consistent with the observed moment and only a third of the formal $d^5$ value. We raise and discuss one important question: Since this AFM ordering is at $q = 0$ (in the 20 atom cell) where nesting is a moot issue, what is the microscopic driving force for ordering and the accompanying MIT?

I. INTRODUCTION

In condensed matter physics the origins of, and phenomena associated with, metal-insulator and magnetic transitions remain issues of fundamental interest, especially when they do not fit into a conventional mold. From this viewpoint, a few 5$d$-based oxides, including the osmate studied here, that display an abundant variety of physical phenomena, including superconductivity, important effects due to large spin-orbit coupling (SOC), unconventional metal-insulator transitions (MIT, the focus of this paper), and unusual magnetic behavior.

Within heptavalent Os⁷⁺ $d^{1}$ systems, the cubic double perovskite Ba₂Na₂OsO₆ is ferromagnetic with an unusually small magnetic moment while maintaining a cubic structure,¹ whereas the magnetic structures of the trigonal Na₂OsO₅ and Li₂OsO₅ and the double perovskite Ba₂LiOsO₆ are based on antiferromagnetic (AFM) order.²⁻⁴ In the hexavalent $d^{2}$ systems, the double perovskite Ba₂CaOsO₆ is ferromagnetic.⁵ At the metallic $d^{2.5}$ oxidation level, KOs₂O₂ is a $\beta$-pyrochlore structure shows superconductivity⁶ at $T_c = 8$ K, whereas the triple perovskite Ba₂Li₂OsO₆ becomes AFM⁷ at 13 K but shows significant reduction in the effective moment of 3.3 $\mu_B$ from the theoretical spin-only value of 4.78 $\mu_B$, suggesting strong SOC effects. In a pentavalent $d^{3}$ system, the slightly distorted double perovskite Sr₂CrOsO₆ is a semimetallic ferrimagnet in which SOC plays a large part in the magnetic behavior by reducing the spin moment by 0.27 $\mu_B$ and inducing an orbital moment of 0.17 $\mu_B$ on the Os ion, decreasing the net moment by nearly a factor of 2.⁸⁻⁹ Pentavalent Cd₂Os₂O₇, with its magnetic frustration on the pyrochlore Os sublattice, has been suggested to be an itinerant Slater insulator,¹⁰ i.e., a MIT induced by antiferromagnetic ordering rather than by strong correlation effects.¹¹,¹² Regarding Slater insulating states, $d^3$ Sr₂IrO₄, with a weakly canted antiferromagnetic MIT¹³ at 250 K, has recently been characterized as a Slater insulator.¹⁴ The character of the noncollinear ordered $d^3$ Cd₂Os₂O₇ is still under discussion.¹⁵

The orthorhombic perovskite NaOsO₃, also with pentavalent Os, synthesized by Shi et al., undergoes a MIT coincident with antiferromagnetic ordering at the rather high temperature of $T_N = 410$ K with no evidence for any further structural distortion below 600 K.¹⁶ The resistivity increases, and the Hall number decreases, by $\sim 3$ orders of magnitude from $T_N$ to 200 K and continued decreasing to 2 K, the insulating character becoming more accelerated below 25 K toward a strongly insulating ground state. The electronic contribution to the specific heat measurement vanished at low temperature, indicating a fully gapped Fermi surface. Due to this uncommon behavior, seemingly a continuously increase of gapping of the Fermi surface leading to a decrease and, finally, a vanishing of carriers, this system was argued to be the first example of the continuous MIT (the so-called Slater insulator with continuous opening of the AFM gap).

Recently, Calder et al. confirmed the continuous transition as a simultaneous change in magnetic and transport character.¹⁷ The effective Curie moment of 2.71 $\mu_B$ observed by Shi et al. is reasonably consistent with a $S = 3/2$ moment, reduced (by 30%) by hybridization with oxygen and perhaps compensated somewhat by an orbital moment. This picture is one of high spin $3^3$ Os⁵⁺.¹⁸ Neutron power diffraction (NPD) measurements indicate G-type antiferromagnetism (G-AFM) with direction of moments alternating on neighboring Os ions,
but an Os ordered moment of only 1 μB. This reduced value is difficult to reconcile with a S = 3/2 picture, since three dimensional arrays of large spins should not be subject to reduction by fluctuations. In the only previous theoretical work on NaOsO₃, Du et al. calculated a similar (even somewhat smaller) value from the sort of first-principles calculations we will describe and use below. The NPD measurements show the spin oriented along the c axis without canting of the spins, which provides additional information related to the impact of large SOC, one aspect that we want to investigate more thoroughly.

Du et al. obtained a magnetic ground state of the observed G-AFM type and provided a comparison of this state to other types of magnetic order that they could obtain in their calculations for NaOsO₃. There remain several unresolved questions: (1) What is the origin and nature of the AFM ordering, and what other states are energetically nearby? (2) Why is the ordered moment only 1 μB for pentavalent Os d⁵? Is strong SOC a factor? (3) Why is this MIT continuous instead of the more common first-order type of MIT in transition metal oxides? (4) Does SOC perhaps play a more central role than is apparent from the results presented by Du et al.? The orientation of the moments (magnetocrystalline anisotropy) may provide useful conditions to address this question.

For another perovskite-based osmate Ba₂NaOsO₆, we observed strong interplay between correlation effects, small bandwidth, and strong SOC that are necessary to consider together to build an interpretation of the unusual features of that system, which include that it is an uncommon ferromagnetic Mott insulator, it displays a very small ordered moment, and it remains cubic when it seems the d⁵ configuration should favor at least a small Jahn-Teller distortion. In this paper, we address most of the questions we raised above, using first-principles spin-polarized calculations, including both correlation effects and SOC.

II. STRUCTURE AND METHODS

Shi et al. reported a highly distorted structure involving relative displacement of Na and O ions, leading to a $\sqrt{2} \times \sqrt{2} \times \sqrt{2}$ quadrupled gadolinium orthoferrite type supercell (space group: Pnma, No. 62, as displayed in Fig. 1). This large structure distortion is consistent with the small tolerance factor $t = 0.87$, using the Shannon ionic radius. This GdFeO₃ structure type has been described in some detail by Pickett and Singh. The lattice parameters are $a = 5.3842$, $b = 7.5804$, and $c = 5.3282$ (in units of Å), corresponding to the volume per formula unit (f.u.) of a cube with edge $3.788$ Å. The atomic positions are given in Table I. This orthorhombic distortion leads to three somewhat different Os – O bond lengths, but all are close to 1.94 Å, resulting in a near-ideal aspect ratio of $\sim 1.002$. Thus the local structure is consistent with the $t_{2g}$ orbitals being equally occupied ($t_{2g}^6$, $S = \frac{3}{2}$), retaining local cubic symmetry in the OsO₆ octahedron. The O – Os – O bond angles are 90.7°, 89.3°, or 89.1°, also indicating nearly ideal OsO₆ octahedra. However, the rotation and tilting of the octahedra are substantial. The O – Os – O axis tilts by 11° relative to the $b$ axis and rotates by 9° in the $a$ (or $c$) axis.

In our work both SOC and correlation effects have been assessed, within LSDA + SOC, LDA + U, and LSDA + U + SOC approaches, implemented in two all-electron full-potential codes FPLO and WIEN2K. (The latter combination is available only in WIEN2K.) To include correlation effects in the half-filled $t_{2g}$ shell, an effective on-site Coulomb repulsion $U_{eff} = U - J$ was used for the results we present, since experience has shown results very similar to those obtained from separate $U$ and the Hund’s exchange integral $J$ inputs when a shell is half-filled. Convergence was checked up to a $14 \times 9 \times 14$ mesh of Brillouin zone sampling. In WIEN2K, the basis size was determined by $K_{max} = 7$, quite adequate for these atoms, and the APW radii were $Na 2.14$, Os 2.15, and O 1.4, in a.u.

III. MAGNETICALLY ORDERED ($T = 0$) PHASE

A. LSDA electronic structure

To begin, we compare electronic structures of the cubic and distorted phases. Within LSDA, the cubic phase has a higher energy by 378 meV/f.u. than the distorted structure in the nonmagnetic (NM) state, reflecting the strong lowering of energy by the distortion alone. The atom-projected densities of states (DOSs) in both phases are compared in the top panel of Fig. 1. The distortions were assessed in the nonmagnetic state, assuming an ideal OsO₆ octahedron. However, the rotation and tilting of the octahedra are substantial. The O – Os – O axis tilts by 11° relative to the $b$ axis and rotates by 9° in the $a$ (or $c$) axis.

of Fig. 2 and are consistent with those presented by Shi et al.\textsuperscript{16} As discussed in Ru-based perovskites by Mazin and Singh,\textsuperscript{24} the OsO\textsubscript{6} octahedra must be understood as oxygen-shared clusters. In the cubic phase, the \( t_{2g} \)–\( p_z \) antibonding (\( pd\pi^* \)) and bonding (\( pd\pi \)) states lie roughly in the \(-2.9 \) to \(1.3\) eV and of \(-8.7\) to \(-4.7\) eV regions, respectively. (The latter complex manifold with the width \( W = 3.5\) eV. The deep pseudogap in the DOS of Fig. 2 results from an incipient gap formation arising as a combination of the distorted lattice and AFM order. The valence (occupied) band complex has become nearly disjoint from the conduction (unoccupied) bands in nearly the entire zone, with slight overlap remaining at the \( Y \) and \( R \) points. The top two occupied bands are quite flat, accounting for the sharp peaks at \(-0.1\) and \(-0.2\) eV as shown in the bottom panel of Fig. 2.

B. Conditions for antiferromagnetic ordering

To probe the effects of the structural geometry on the AFM state, we varied both the volume and the angles of the OsO\textsubscript{6} octahedral rotation. In the cubic structure with the same volume as the experimentally observed structure, no AFM order could be obtained. To check further for magnetic order in the cubic phase, the lattice parameter of the cubic phase was varied in the range of \( \pm 3\% \). No magnetic order was obtained, indicating that the AFM order is not induced by simple variation of the Os–Os distance. Also, as expected, no AFM order is induced by Na displacement.

Next we varied the two structural angles individually. At a critical tilt of \( \theta_c = 3^\circ \), a hybridization gap between \( pd\pi^* \) and \( pd\sigma^* \) manifolds appears, accompanied by AFM ordering.
with an Os moment of 0.26 $\mu_B$. Somewhat unexpectedly, this moment remains unchanged up to $\theta = 11^\circ$, the observed tilt angle. When rotating the octahedra by $\phi$, AFM with $M_{Os} = 0.13 \mu_B$ appears at $\phi = 9^\circ$, where the overlap between the $pd\pi^*$ and $pd\sigma^*$ manifolds becomes very small. In all cases the opening of a hybridization pseudogap around the Fermi level accompanies the AFM order, establishing a close connection in this compound between structure and magnetic order.

C. Metal-insulator transition versus $U_{\text{eff}}$

Now we focus more closely on correlation effects beyond LSDA on the AFM state in the observed distorted structure, by applying the on-site Coulomb repulsion $U_{\text{eff}}$ to Os ions using the LDA + $U$ method. As might be anticipated from the pseudogap at $E_F$ at the required band filling, a gap opens for $U_{\text{eff}}$ as small as 1 eV. The Os local moment is 1.0 $\mu_B$, consistent with the experimentally observed value.\textsuperscript{15} This value is nearly unchanged when SOC is included (see below). Considering $5d^3$ Os$^{5+}$ ions, the naive expectation based on a localized $5d$ orbital is that orbital and spin ordering of $t_{2g}^5 t_{2g}^1$ (corresponding to a highly unusual spin density) would be required to obtain this reduced value of moment. In the insulating state, the spin density, however, assumes a local cubic symmetry dimpled dice shape, shown in Fig. 4, which confirms equal occupation of the $t_{2g}$ orbitals.

At $U_{\text{eff}}^c$, the $d$ occupation matrix substantiates this conclusion. The majority $t_{2g}$ orbitals are almost equally occupied at about 0.7e per orbital, substantially reduced from the formal value of unity. The majority $e_g$ and all the minority $d$ orbitals, which are formally unoccupied, each have occupation of about 0.3e per orbital, reflecting substantial $p-d$ hybridization and indicating a strong deviation from the conventional ionic $d^3$ viewpoint. In total, there are 4.3 electrons throughout the $d$ orbitals, instead of the formal value, 3. This “discrepancy” is not so surprising, as it is widely recognized that an actual charge on $d$ cations differs from the formal charge, sometimes\textsuperscript{20} by a factor of 2. For Os here, the formal charge of $+5$ is contrasted with an actual charge of around $+3.7$. The reduction by a factor of 3 of the formal moment is a more notable feature and, unlike the case of Ba$_2$NaOsO$_6$ where the moment is also vastly reduced,\textsuperscript{9} here it is unrelated to SOC. NaOsO$_3$ is a case of an insulating transition metal oxide where the formal charge (oxidation state) picture is murky at best.

The corresponding band structure at $U_{\text{eff}}^c$ is displayed in Fig. 6. The SOC splitting is about 0.2 eV at the $\Gamma$ point. An unusual outcome of the structural distortion is that the top of the valence bands is nearly flat, reflected in the step increase

![FIG. 4.](Image) (Color online) Spin density plot of Os ions in the $a$-$c$ plane, with isosurface at 0.13 e/Å$^3$. This is obtained in LDA + $U$ at $U_{\text{eff}} = 1$ eV, where this system becomes insulating, and reflects locally cubic symmetry. The different color indicates the opposite spin orientation in the G-AFM alignment.

FIG. 5. (Color online) Direct and indirect gap vs effective $U$ in LSDA + $U$ + SOC calculations. Below the critical value of $U_{\text{eff}} = 2.2$ eV, the indirect gap becomes negative, i.e., the bands are semimetallic.

consistent with the itinerancy evident in the electronic structure and apparently in the MIT as well.

Figure 5 shows change in the direct and indirect gaps due to varying $U_{\text{eff}}$. In the distorted structure and including SOC, an energy gap opens only at $U_{\text{eff}}^c = 2.2$ eV.\textsuperscript{27} Above $U_{\text{eff}}^c$, both gaps increase linearly at a rate of 0.16 eV/eV, with the difference of 0.3 eV independent of $U_{\text{eff}}$. Below $U_{\text{eff}}^c$, a negative indirect gap (not shown) results due to significant lowering of the bottom of the conduction band at the $\Gamma$ point, though the direct gap is already established (the occupied and unoccupied bands are disjoint). This feature may be related with the proposal of a continuous transition in opening an energy gap, as discussed in another osmate Cd$_2$Os$_2$O$_7$ by Shinaoka et al.\textsuperscript{12} Considering a likely $J \approx 0.5$ eV, $U^c \approx 2.7$ eV $\sim W$ suggests, for this multiband system, that a Mott transition is not the appropriate picture for this continuous MIT.

The corresponding band structure at $U_{\text{eff}}^c$ is displayed in Fig. 6. The SOC splitting is about 0.2 eV at the $\Gamma$ point. An unusual outcome of the structural distortion is that the top of the valence bands is nearly flat, reflected in the step increase

FIG. 6. Enlarged AFM band structure of Os $t_{2g}$ manifold at $U_{\text{eff}} = 2.2$ eV in LSDA + $U$ + SOC. A gap opens at $U_{\text{eff}} = 1$ eV in the LDA + $U$, but $U_{\text{eff}} = 2.2$ eV is required when SOC is included.
in the valence band DOS evident in Fig. 7, and provides a two-dimensional character to the low-energy phase space. We also point out that the dispersion is very similar above and below \( E_F \), relevant information for yet-to-be-done optical experiments since the \( k \)-conserving joint DOS may be sharply peaked at the onset of absorption. Within LSDA + U + SOC as in LSDA, the AFM state is nearly degenerate with the NM state. The fact that neither state is energetically favored is consistent with the finite temperature transition between the two states.

The value of \( U \) appropriate for NaOsO\(_3\) has already been mentioned in the literature, in addition to the conclusion \( U \approx 2 \) eV of Du \textit{et al.} that is nearly identical to ours. Calder \textit{et al.} reported data on magnetic x-ray resonant scattering (MXRS) with interpretation from x-ray absorption near edge spectra (XANES) obtained from Joly’s finite difference code\(^{28}\). They obtained a better correspondence using \( U \) method, the effect of SOC on the atom-projected DOS may be sharply peaked at the onset of absorption. Within LSDA + U + SOC as in LSDA, the AFM state is nearly degenerate with the NM state. The fact that neither state is energetically favored is consistent with the finite temperature transition between the two states.

D. Additional effects of spin-orbit coupling

As discussed for several decades, \( t_{2g} \) orbitals, when split off from the \( e_g \) orbitals by the crystal field, form a representation of an angular momentum of \( L = 1 \)\(^{11}\). In the locally cubic geometry and half filling, the orbital moment should be small. As shown in Table II, inclusion of SOC leads to an orbital moment antialigned with the spin moment and with magnitude no larger than \( 0.1 \) \( \mu_B \). Thus, in the insulating state, the net moment remains about \( 1 \) \( \mu_B \), consistent with the experimentally observed value\(^{17}\) and relatively insensitive to \( U_{\text{eff}} \) in the range studied here (see Table II).

We have calculated total energies with LSDA + U + SOC with four spin orientations (100), (010), (001), and (111) to determine the easy axis. As observed by Calder \textit{et al.},\(^{17}\) (001) is the easy axis. Along (010), both spin and orbital moments increase by 10% in magnitude, but the energy cost is large, 474 meV/f.u., despite some additional Hund’s coupling energy. Along (111), the spin moment is enhanced to 1.25 \( \mu_B \) while the energy is higher by 51 meV/f.u. Consistent with the similarities between the \( a \) and \( c \) axes (the octahedron rotation is around the \( b \) axis) the energy difference is small, only 5 meV/f.u.

IV. FINITE TEMPERATURE, METAL-INSULATOR TRANSITION

Approached from high temperature, a continuous MIT occurs at the point where the spin-symmetric phase becomes unstable to magnetic order, which is AFM order in the case of NaOsO\(_3\). In Slater-type (itinerant) transitions, ordering conventionally is driven by Fermi surface (FS) nesting, as in the classic case of chromium. The common picture for a Slater MIT is that a spin density wave (SDW) gaps at least a portion of the FS, and the increasing amplitude of the SDW destroys more and more of the FS as the temperature is lowered. The specific heat data for NaOsO\(_3\) indicate the FS is completely gone as \( T \to 0 \). The resistivity data strongly suggests it has been effectively destroyed at intermediate temperature, since the magnitude and temperature coefficient reflect insulating behavior even as spin-fluctuation scattering has begun to be frozen out by the magnetic order (which, in itself, should lower rather than increase the resistivity), and the strongly decreasing Hall coefficient is consistent with rapidly shrinking FSs. In this section we, first, discuss the electronic structure in the (high temperature) nonmagnetic metallic state, albeit without consideration of the thermal broadening and the lattice dynamical and spin fluctuation scattering that may be necessary for a detailed picture. We then provide a scenario for the MIT that is consistent with observations and what is understood about the electronic structure.

A. Electronic structure in the nonmagnetic phase

The LSDA and LSDA + SOC band structures without magnetic order are displayed together in Fig. 8. We have checked that including \( U_{\text{eff}} \) in this nonmagnetic phase leads to negligible effect, as is commonly observed. In the previous section we established that SOC has relatively little impact on the bands in the AFM phase, displaying its main impact by its seeming competition with correlation effects so the correlation strength necessary to open the gap (within the AFM phase) is doubled to \( \sim 2 \) eV. Near \( E_F \), the effect of SOC on the
FIG. 8. (Color online) Enlarged view of the nonmagnetic $t_{2g}$ band structures appropriate to the high-$T$ nonmagnetic phase in LDA (red dashed lines) and LDA + SOC (black solid line). Including $U$ makes negligible difference. Inset: Nonmagnetic total DOSs in LDA (red dashed lines) and LDA + SOC (black solid lines) near $E_F$ (in states/eV-f.u.).

band structure (Fig. 8) in the high-$T$ phase again seems minor, but it is clearly visible at symmetry points (Y, S) where it removes degeneracies and splits bands. Moreover, the effect on the DOS is minor, as is clear from the inset of Fig. 8. With or without SOC, the Fermi level DOS $N(E_F) \approx 3$ states/eV-f.u. for both spins, corresponding to a linear specific heat coefficient $\gamma = 7$ mJ/mol-K$^2$. This standard metallic value is corroborated by large FS sheets, which we now discuss.

Because the topology of the FSs is central to a SDW transition, we display FSs without and with SOC in Fig. 9. The small shifts in band energies due to SOC that can be seen in Fig. 8 are translated by the small velocities into considerable changes in the complex multisheeted FSs, with some of the clearest changes occurring around the symmetry points. The FSs retain to some extent an approximate fourfold symmetry in the $a$-$c$ plane ($x$-$y$ plane in Fig. 9), which, of course, is not a true symmetry of the $Pnma$ structure but is useful to recognize. There are both electron- and hole-type surfaces, making the magnitude of the Hall coefficient difficult to interpret.

**B. Comments on the metal-insulator transition**

Most theoretical work on AFM transitions in metals, including very recent ones, focus either on FS nesting (Cr is the classic example) or FS “hot spots” involving band and FS folding due to the finite-$q$ order that set in at the transition. In the first case the nested sections of FS become gapped, while in the second case the FS also reconstructs but in a less obvious manner. For example, Sachdev et al.\textsuperscript{29} review the latter scenario and provide evidence of a breakdown of fermionic quasiparticle excitations at the transition, and a FS reconstruction from large to small surfaces that have been discussed for many years in the high-temperature superconducting cuprates.

Both the nesting scenario and the hot-spot scenario of the continuous Slater transition to an AFM incurs difficulty in NaOsO$_3$, because it is a $q = 0$ ordering for which both scenarios, which focus on a nonzero wave vector $Q_{AF}$, become moot. This situation can arise, and not uncommonly, in crystal structures with more than one magnetic ion of a given type. In NaOsO$_3$, the four symmetry-related Os ions in the GdFeO$_3$ distorted lattice devolve into two pairs, with spins in opposite directions. Interestingly, the original exposition by Slater\textsuperscript{10} did not involve finite-$q$ physics in any explicit manner. His picture, based on spin-unrestricted Hartree-Fock theory, was that AFM ordering would introduce new Fourier components in the (spin-dependent) potential, leading to new gaps in the band structure that could well appear at the Fermi level, especially in stoichiometric compounds where there is the likelihood that bands can be completely occupied or completely unoccupied. If the new gaps appear at a zone boundary, it will be energetically favored to double the periodicity, as in the simplest picture of SDW order. Yet if the new gaps appear only at $q = 0$ (no cell doubling), the band structure may still become gapped in spite of the lack of any extension of periodicity.

The effect of AFM ordering in NaOsO$_3$ on the electronic structure can be seen by comparing the metallic bands of the nonmagnetic high-$T$ phase in Fig. 8 (solid lines) with the AFM insulating bands in Fig. 6. New Fourier components of the potential separate the bands strongly at zone boundary symmetry points (viz., R, Y, S) and at the zone center the bands are already split. Slater also tied this type of ordering to bonding-antibonding band formation, which provides a band
energy (bonding energy) gain in addition to the Hund’s rule (magnetic) gain in energy.

A rudimentary picture that is consistent with data and with this understanding of the electronic structure can be assembled. Already at high $T$ the strongly distorted, four f.u. per primitive cell, structure is dictated by the tolerance ratio of $0.87$. The distortion leaves flat bands at and near the FS, which is large and multilayered. At $T_N$, magnetic order sets in and the metallic band structure begins to morph continuously toward the $T = 0$ AFM insulating band structure. The FSs, both electron and hole types, begin to shrink in volume and vanish one by one, until no FS remains. The change from the metallic to the insulating band structure should be monotonic in, and nearly proportional to, the magnetic order parameter. The magnetic order parameter measured by Calder et al. was provided only down to $\sim 0.85 T_N$, so it is not possible to estimate when the last FS may be expected to disappear. As mentioned earlier, thermal smearing and lattice and spin fluctuations will complicate a detailed picture. One loose end in this picture is the apparent discontinuity—a jump by roughly 50%—in the paramagnetic susceptibility just below $T_N$.

Without a Fermi surface or hot-spot origin, the mechanism of G-type ordering is not clear and was not addressed by Du et al. in their theoretical study of magnetic ordering. Since G-type ordering is common in perovskite transition metal oxides, it seems likely this ordering represents an emergence of the nearest-neighbor AFM coupling commonly occurring in perovskites, in spite of the apparent itineracy in the electronic structure and the collapse of the $d^3$ valence state picture.

V. SUMMARY

Our results have clarified a number of features of NaOsO$_3$, and the questions posed in Sec. I. First, a combination of the distortion of the perovskite structure and moderate correlation effects is responsible for both antiferromagnetism and the insulating gap in the ground state. Our calculations account naturally for the factor of three reduction in the observed moment ($\mu_B$) relative to the ideal $\mu_B$ value, due to very strong hybridization with the O 2$p$ orbitals that render the conduction states, and the magnetism, itinerant in nature. The oxygen ions, being coordinated with two Os ions with antialigned spins, are unpolarized by (approximate) symmetry. The calculated energetics, with small energy difference between the magnetic and nonmagnetic states, is also consistent with a Slater-type metal-to-insulator transition to an AFM state. Moreover, the simplest specification of a Mott insulator is one in which the insulating state does not depend on magnetic order. In NaOsO$_3$ all the evidence indicates that magnetic order is necessary for insulating behavior. Because of the itinerant nature of the moment, a Heisenberg model cannot provide a representation which could then be applied to predict the Néel temperature.

Spin-orbit coupling, often a dominant force in 5$d$ metal oxides, has a more modest effect in this compound. While it affects the band structure enough that the effective coupling strength $U_{eff}$ is increased from 1 to 2.2 eV, it is in itself ineffective in decreasing the local moment. The strong moment reduction (from a localized high-spin $t_{2g}$ picture of 3 $\mu_B$) is due to strong hybridization with O 2$p$ orbitals—that is, itineracy—which is itself affected by the distortion. The minor importance of SOC is consistent with the finding of Calder et al. that x-ray resonant photoelectron spectra show only minor effect of SOC.

Though 3$d$ perovskite oxides have been studied extensively for decades, their 5$d$ counterparts are relatively new to detailed inspection of their properties and the underlying mechanisms. Our results for NaOsO$_3$ will help to provide a basis for understanding the distinctions in the physics of 5$d$ versus 3$d$ (and 4$d$) oxides.

27 In Ref. 18, Du et al. quoted $U^* = 2$ eV, without mentioning $J$ explicitly. Considering that they also used WIEN2K, this value seems to be $U^\text{eff}$, which is consistent with our results.
